ENERGY AND WIDTH MEASUREMENTS OF LOW-Z
PIONIC X-RAY TRANSITIONS*

NSG-567

- -

New measurements have been performed of the energies and natural line widths of 2p-1s pionic X-ray transitions, as well as muonic transition energies, in Li^6, Li^7, Be^9, B^{10}, B^{11}, and C^{12}. High-resolution Si(Li) and Ge(Li) spectrometers were used, resulting in a more precise determination than previously reported of the transition energies and natural line widths. Comparison of the measured complex energy shifts in the pionic transitions has been made with the theory of the Ericsons and good agreement found.

- -

Several measurements[1,2] of the energies and natural line widths of pionic 2p-1s X-ray transitions have recently been given in the literature. We wish to report new and more precise measurements, in addition to theoretical calculations, for pionic transitions in Li^6, Li^7, Be^9, B^{10}, B^{11}, and C^{12}.

Most of the data was obtained using a 75-MeV negative pion beam (with approximately 15% muon contamination) at the Carnegie-Mellon synchrocyclotron, a small portion being obtained with a 100 MeV beam at the Space

Radiation Effects Laboratory (SREL). Each of these pion beams was focussed into a scintillation counter array and standard coincidence techniques insured that the 1600-channel analyzer used to sort and store pulses from the Si(Li) or Ge(Li) detector did so only when a fast timing coincidence existed between the π-stop signal and the detector signal. Some of the more important experimental considerations were:

(1) the detector used with each of the elements was chosen on the bases of both resolution and efficiency requirements. For the Li^6, Li^7, and Be^9 targets, the 80 mm^2 x 3 mm Si(Li) detector was used; for B^{10}, B^{11}, and C^{12}, the 3.5 cm^2 x 5 mm Ge(Li) detector.

(2) the detectors were operated out of the direct beam so as to minimize pulse pile-up problems.

(3) calibration runs of the detection system, using well-known lines of Am^{241} and Ta^{182}, were taken before and after each X-ray run.

(4) for runs with the Ge(Li) spectrometer, which was used for the energy range of 50-100 keV, gain drifts were minimized by use of a digital gain stabilizer whose reference peak was the 59.57 keV γ-ray line of Am^{241}.

The instrumental resolutions of the cooled FET Si(Li) and Ge(Li) spectrometers under beam conditions were respectively 0.62 keV (FWHM) at 33 keV and 1.1 keV (FWHM) at 75 keV, as determined from muonic X-rays. These figures represent less than a 10% degradation in resolution as

previously determined with radioactive sources under laboratory conditions. The operation and characteristics of these spectrometers have been described elsewhere[3,4].

Muonic X-ray lines were present in the π runs because of the muon contamination in the beam and constituted a substantial background because of the relatively low yield of pionic 2p-1s transitions. However, in most cases, spectrometer resolution permitted unambiguous separation of the pionic 2p-1s peaks and the more intense of the contaminating muonic lines. Fig. 1 illustrates raw pionic and muonic X-ray data for a "π"-beam run in Be^9 (Si[Li] detector). The $\mu-K_\beta$ background line, lying approximately 3 keV below the respective primary $\pi-K_\alpha$ peak, is clearly separated from the pion peak. In order to account properly for those muonic lines which appeared <u>directly under</u> the pionic lines, separate μ-beam data were accumulated. This permitted an independent determination of the relative intensities of the $\mu-K_\alpha$, $\mu-K_\beta$, $\mu-K_\gamma$, and $\mu-K_\delta$ lines which were used in the background subtraction analysis for the pionic X-ray data.

Briefly, the major features of the analysis for the 2p-1s pionic peaks were:

(1) subtraction of the muon contaminating lines under the pionic X-ray peaks.

(2) determination of the center channels of the pionic peaks by fitting the contaminant-free pionic data to both Gaussian and Lorentzian functions and a linear background term. For a given peak, the center channel value obtained

from each of these two fits was the same within the statistical error.

(3) determination of the natural line widths by using Voigt profiles (convolution integrals of a Gaussian and a Lorentzian function) to fit the pionic data. It should be noted that, in contrast to extracting a center channel value, the determination of the natural line width was very shape-dependent, as verified by the differences in widths obtained from separate Gaussian and Lorentzian fits.

(4) use of a precision pulser to determine uncertainties introduced into the energy measurements as a result of system non-linearities.

The experimental results for the measured transition energies and natural line widths are given in Tables I and II. The errors quoted include statistical uncertainties as well as the uncertainties in background subtraction and system linearity. The agreement between the corresponding measured energies given in Table IA is, in general, quite satisfactory. The values of E_{calc} quoted for the 2p-1s pionic transition energies were obtained by correcting the Klein-Gordon value for (a) vacuum polarization effects (including finite size) according to the method of Mickelwait and Corben[5] and (b) Coulomb effects using Pustovalov's technique[6] with nuclear radii determined from electron scattering data[8-14]. The difference between E_{calc} and E_{exp} constitutes the measured nuclear shift E_{nuc}.

The theoretical values of E_{nuc} have been obtained from the work of Ericson and Ericson[15,16]. An expression for the complex energy shift is obtained by them in expansion form by solving the Schrodinger equation for an optical potential with constant parameters representing the pion-nucleus interaction. The constant parameters which specify the single-nucleon potential primarily responsible for the level shifts were obtained from π-N scattering data and have been corrected, as outlined by the Ericsons[16], for nuclear binding, Fermi motion, finite nuclear correlation lengths, and the shift induced by the real part of the two-nucleon potential. The estimated error on the theoretical values of E_{nuc} is 20-30% and is primarily due to the uncertainty in the two-nucleon correction. Within this uncertainty, agreement between the experimental and theoretical values of E_{nuc} is quite good.

The nuclear radii listed in Table IB were obtained following the method of Jenkins et. al.[1], in which the measured muonic transition energies are compared with the corresponding Dirac values after correction for vacuum polarization. The radii computed from our muonic X-ray data are compared in Table IB with the values obtained from electron scattering data, the latter being more precise for these light nuclei.

Table II consists of experimental results of the natural line widths Γ_n obtained by us and other workers, in addition to theoretical values for Γ_n. With the exception of the Be^9 and B^{10} widths, the agreement between the experimental results is satisfactory, this work being more precise. The theoretical values of Γ_n have also been calculated from the complex

energy shift given by the Ericsons [15,16]. The parameters specifying the two-nucleon potential were obtained from 2N pion production data and have been corrected for binding, Fermi motion, and 1/A spin-isospin effects. It should be noted that the pion s-wave interaction amplitude β_{11} describing absorption onto two nucleons in a relative triplet state is different in value from that given by the Ericsons. The value used by the Ericsons was obtained from an early measurement [17] of the cross section for the reaction $p + p \rightarrow \pi^+ + d$ in an energy range where the p-wave interaction dominates. The value of β_{11} used in our calculation is presumably more reliable since it was taken from the more recent measurement [18] of the $\pi^+ + d \rightarrow p + p$ cross section at low energies where the s-wave interaction dominates. Use of the older value of β_{11} would result in calculated widths which are approximately 35% lower than those shown in Table II. We estimate a 15% error in the calculated widths and, as is true for the level shifts, there is good agreement between the experimental and theoretical results.

Finally, it should be noted that first-order perturbation theory with hydrogen-like wave functions closely approximates the theoretical values for both the energy shifts and widths listed in Tables I and II, respectively. Perturbation theory results in shifts and widths which are respectively 15% and 4% larger than the listed theoretical values. These results contradict the conclusion of Seki and Cromer [19] based on earlier width measurements that first-order perturbation theory is invalid for analysis of low-Z pionic atoms.

TABLE I

A. 2p-1s pionic X-ray energies (in keV).

Element	E_{exp}		E_{calc} [a]	E_{nuc}	E_{nuc} [a]
	This Work	*Earlier Work		(measured)	(theoretical)
Li^6	24.18±0.06	23.9 ±0.2[b]	24.53	0.35±0.06	0.47
Li^7	24.06±0.06	23.8 ±0.2[b]	24.63	0.57±0.06	0.79
